**ABSTRACT:** Previous high-pressure experiments have shown that pressure-transmitting fluids composed of small molecules can be forced inside the pores of metal organic framework materials, where they can cause phase transitions and amorphisation and can even induce porosity in conventionally non-porous materials. Here we report a combined high-pressure diffraction and computational study of the structural response to methanol uptake at high pressure on a scandium terephthalate MOF ( $\text{Sc}_2\text{BDC}_3$ ,  $\text{BDC}=1,4$ -benzenedicarboxylate) and its nitro-functionalised derivative ( $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$ ) and compare it to direct compression behaviour in a non-penetrative hydrostatic fluid, Fluorinert-77. In Fluorinert-77,  $\text{Sc}_2\text{BDC}_3$  displays amorphisation above 0.1 GPa, reversible upon pressure release, whereas  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$  undergoes a phase transition ( $C2/c$  to  $Fdd2$ ) to a denser but topologically-identical polymorph. In the presence of methanol, the reversible amorphisation of  $\text{Sc}_2\text{BDC}_3$  and the displacive phase transition of the nitro-form are completely inhibited (at least up to 3 GPa). Upon uptake of methanol on  $\text{Sc}_2\text{BDC}_3$ , the methanol molecules are found by diffraction to occupy two sites, with preferential relative filling of one site compared to the other: grand canonical Monte Carlo simulations support these experimental observations and molecular dynamics simulations reveal the likely orientations of the methanol molecules, which are controlled at least in part by H-bonding interactions between guests. As well as revealing the atomistic origin of the stabilization of these MOFs against non-penetrative hydrostatic fluids at high pressure this study demonstrates a novel high pressure approach to study adsorption within a porous framework as a function of increasing guest content, and so to determine the most energetically favorable adsorption sites.

## INTRODUCTION

Porous metal organic framework solids are of great current interest because of their potential applications and their chemical and structural variety, which lead directly to novel chemical and physical properties.<sup>1</sup> Their high surface areas, comprising internal pore surfaces that offer shape selectivity, variable hydrophobicity, accessible cations and organic functional groups, offer well-defined and readily tuneable materials for molecular uptake, separation, storage and delivery, and in some cases catalytic conversion.<sup>2,3</sup> Furthermore, their complex structures are in many cases responsive to external stimuli such as temperature, light and pressure.<sup>4,5</sup> Examination of the structural changes of microporous MOFs with increasing pressure is of fundamental interest, because it reveals details of bonding within the framework and, where ingress of the pressure-transmitting fluid occurs, of framework-guest (and guest-guest) interactions. Further, efficient application of MOFs at high pressure, for example in gas storage and separation, and as stationary phases in HPLC, will also require an understanding of the effect of high pressures on both framework and framework-guest structure.<sup>6</sup>

Diffraction studies, both X-ray and neutron, have yielded important information on both the response of frameworks to adsorption and the binding sites of guest molecules.<sup>7-9</sup> Where possible, single crystals have been studied because of the greater amount of structural data they afford, although there remains a relative paucity of structural data concerning adsorbate location in MOFs, so that even for molecules such as  $\text{CO}_2$  that are of great current interest, only 66 entries within the Cambridge structural database exist (November 2012 release).<sup>10</sup> Even fewer studies have examined the response of single crystals of MOFs to high liquid pressures, because more specialised diamond anvil cell (DAC) apparatus is required, though recent computational studies have been performed.<sup>11</sup> Previously, the crystal structures of the porous MOFs MOF-5 (zinc terephthalate), Cu-BTC (copper trimetate) and the zinc zeolitic imidazolate framework ZIF-8 have been measured between 1-3 GPa (*ca* 10,000-30,000 bars), with more dense MOFs such as ZAG-4 ( $\text{Zn}(\text{HO}_3\text{PC}_4\text{H}_8\text{PO}_3\text{H})\cdot 2\text{H}_2\text{O}$ ) have been studied to much higher pressure (*ca* 100,000 bars).<sup>12-15</sup> In these studies, the sample (single crystal or polycrystalline powder) was loaded into the DAC chamber and surrounded by either

Fluorinert FC-77 (a mixture of perfluorooctane ( $C_8F_{18}$ ) and perfluorooxacyclononane ( $C_8F_{16}O$ )), diethylformamide, a 4:1 by volume mixture of methanol:ethanol, or a 16:3:1 methanol:ethanol:water mixture as hydrostatic liquids. Initial application of pressure to all three MOFs using a hydrostatic liquid comprising molecules small enough to enter the pores caused the frameworks to expand. Increasing pressure further resulted in more solvent molecules entering the pores, causing them to become ‘super-filled’ with guest molecules, although with an associated decrease in the unit cell volume from its maximum value. However, because of the large size of the cages present in MOF-5, Cu-BTC and ZIF-8, and the inherent disorder in the location of the adsorbate molecules, it was not possible to determine atomic positions of the adsorbed molecules in these cases.

The scandium terephthalate MOF, scandium 1,4-benzenedicarboxylate ( $Sc_2BDC_3$ ) has a 3D framework structure, unique to this trivalent metal, with a high density of BDC groups linking isolated  $ScO_6$  octahedra.<sup>16</sup> Projected down the  $a$ -axis in the orthorhombic (room temperature) form of  $Sc_2BDC_3$ , the triangular channels (*ca.* 4 Å in free diameter) appear one dimensional (Figure 1a), but there are small gaps in the ‘walls’ of these channels between adjacent BDC ligands. Two symmetry-independent BDC molecules exist; the first is bisected by two perpendicular 2-fold axes and penetrated by a third (Group 1, Fig. 1b), while the other has an inversion centre at the centre of the BDC ring (Group 2, Fig. 1c). The windows formed between pairs of Group 1 and Group 2 linkers form interconnecting channels along the  $c$ - and  $b$ -axis directions respectively, giving rise to a three dimensionally porous framework structure. The pores are hydrophobic - after synthesis they contain no solvent or water molecules. The relatively high porosity of  $Sc_2BDC_3$  and its thermal and chemical stability, together with its tendency to form high quality single crystals make it a model MOF system for studies of small molecule adsorption. In situ diffraction studies of  $Sc_2BDC_3$  at low temperatures (*ca.* 230 K) and moderate gas pressures (1 – 5 bar) have located small gas molecules such as  $CO_2$  and light hydrocarbons physisorbed in the pores, and determined that upon  $CO_2$  uptake the structure relaxed to better coordinate the adsorbate molecules, with a resultant displacive phase transition and associated symmetry change ( $Fddd$  to  $C2/c$ ).<sup>17</sup> The spatial constraints imposed by the narrow pores on the configuration and packing of adsorbate molecules are partly responsible for their ordering and subsequent accurate location by diffraction. A similar approach, in which compounds have been adsorbed into MOFs and their structure determined as part of the resultant guest-host complex has recently been exploited to determine the molecular structure of compounds available only on the nanogram scale or which cannot readily be crystallised.<sup>18</sup>

Here we report structural studies of  $Sc_2BDC_3$  at very high pressures in the presence of different hydrostatic liquids that are either non-penetrative (fluorinated hydrocarbon) or adsorbing (methanol). Whereas the empty structure shows reversible amorphisation at elevated pressures, the methanol-containing structure is greatly stabilised, and is the first ‘high pressure’ example where the adsorbates are located crystallographically and the host-guest and guest-guest interactions explored and elucidated by complementary computer simulation.

It is also possible to prepare single crystals of the nitro-functionalised analogue of this structure,  $Sc_2(NO_2-BDC)_3$  by direct synthesis. The presence of the bulky nitro groups causes the framework to distort to monoclinic  $C2/c$  symmetry to accommodate them, with associated reduction in the free space. The nitro groups block the channels to  $N_2$  uptake at 77 K, but permit some uptake of  $CO_2$  at 273 K.<sup>16</sup> Our high pressure studies of this nitro-functionalised scandium MOF show very different behaviour to that of the unfunctionalized form, for it undergoes a high pressure phase transition that results in a strong volume decrease when

empty, but this is inhibited by methanol uptake over the pressure range explored.

Taken together, these high-pressure structural studies of the parent and the functionalised  $Sc_2BDC_3$  MOF represent the first ever reported inclusion of ordered guest molecules into the pores of a MOF as a function of high-pressure, and reveal both the atomistic ordering of adsorbates in the pores and the resulting stabilisation of frameworks against major structural changes.

**Figure 1.** (a) Triangular pores formed in  $Sc_2BDC_3$  viewed along the  $a$ -axis. Disordered methanol molecules are represented by solid red (Site 1) and blue (Site 2) coloured molecules. Key: C, grey;  $ScO_6$  octahedra, green; O, red; H, light grey.

## EXPERIMENTAL

Single crystals of  $\text{Sc}_2\text{BDC}_3$  and its nitro-derivative were prepared via solvothermal and hydrothermal routes, respectively.<sup>16,19</sup> Crystals of  $\text{Sc}_2\text{BDC}_3$  and  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$  were loaded individually into a modified Merrill-Bassett diamond anvil cell (DAC) along with a ruby crystal (to act as a pressure calibrant). Both crystals were surrounded with a liquid in order to ensure pressure was applied hydrostatically to the crystals. In the first experiments on each crystal type, high-pressure experiments were performed using a non-penetrating hydrostatic medium, the fluorinated hydrocarbon Fluorinert FC-77 (a mixture comprised of perfluorooctane ( $\text{C}_8\text{F}_{18}$ ) and perfluorooxacyclononane ( $\text{C}_9\text{F}_{16}\text{O}$ )) whereas a second set of experiments were performed using methanol as the pressure medium, which was found to enter the pore system of these MOFs. For comparison, the structure of  $\text{Sc}_2\text{BDC}_3$  was also measured at room temperature when immersed in liquid methanol without externally applied pressure. In addition, the adsorption (and desorption) isotherms of methanol from the vapour phase was measured on a Hiden IGA2 gravimetric analyser for  $\text{Sc}_2\text{BDC}_3$  and  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$  at 303 K and 298 K up to the saturation pressures at these temperatures.

Complementary grand canonical Monte Carlo (GCMC)<sup>20</sup> simulations were performed in order to study the order in which adsorption sites are filled by methanol molecules in  $\text{Sc}_2\text{BDC}_3$ , while molecular dynamics<sup>17</sup> simulations were performed in order to elucidate the pore filling mechanism. For more details see the SI.

## RESULTS AND DISCUSSION

**Compression of  $\text{Sc}_2\text{BDC}_3$  using Fluorinert FC-77.** On loading a crystal of  $\text{Sc}_2\text{BDC}_3$  in Fluorinert FC-77 to 0.1 GPa, the unit cell volume decreases by  $39 \text{ \AA}^3$  (0.6 %) compared to the ambient pressure ‘empty’ structure. On increasing the pressure further to 0.4 GPa, a crystalline-to-amorphous phase transition took place which was accompanied by an optical change in the crystal from colourless to opaque (Fig. 2a). The Raman spectra collected within the fingerprint region of the spectra ( $100$  to  $1300 \text{ cm}^{-1}$ ) were almost identical (Fig. S1), which suggests that the local structure of  $\text{Sc}_2\text{BDC}_3$  in the amorphous phase is retained. The pressure was released to ambient pressure and the crystal returned from opaque to colourless (Fig. 2b). Single-crystal X-ray diffraction data collected on the recovered crystal confirmed that the amorphization was fully reversible, with the structure reverting back to the original crystalline phase. The fact that the transition is reversible further supports the assumption that the framework remains intact during the transition. The phenomenon of pressure-induced amorphization has been known for several years, with amorphous ice being the most well-known example.<sup>21</sup> Reversible pressure-induced amorphization has been observed previously in zeolites which have the LTA structure type<sup>22</sup> and inorganic materials such as  $\text{CsAuI}_3$ <sup>23</sup> and  $\text{Ge}_2\text{Sb}_2\text{Te}_5$ <sup>24</sup>. More recently, the reversible pressure-induced amorphization of the dense zeolitic imidazole framework ZIF-4 ( $[\text{Zn}(\text{Im})_2]$ , Im = imidazolate) was observed between 0.35-0.98 GPa for the evacuated sample, or 1.49-4.54 GPa for the solvent-containing sample.<sup>25</sup> The compressibility behaviour observed here in  $\text{Sc}_2\text{BDC}_3$  is therefore very similar to that observed in ZIF-4, with the crystalline-amorphous phase transition observed upon direct compression of the bare framework at low pressures (*ca.* < 1 GPa; similar to the evacuated sample of ZIF-4). Not all MOFs exhibit reversible crystalline-amorphous transitions. In ZIF-8 and MOF-5, amorphization is irreversible.<sup>26,27</sup> The smaller pore nature (and higher density) of  $\text{Sc}_2\text{BDC}_3$  would therefore appear to afford it some resilience to amorphization at lower pressures on directly compressing the crystalline phase. This is clearly an area worth investigating further as irreversible transitions tend to have a detrimental effect on

the adsorption capabilities of MOFs, but this is outside the scope of this study.

**Figure 2.** Optical image of  $\text{Sc}_2\text{BDC}_3$  (lower crystal) loaded in Fluorinert FC-77 at (a) 0.40 GPa and (b) 0.10 GPa after decompression. The colourless crystal sitting above  $\text{Sc}_2\text{BDC}_3$  is a chip of ruby, which is used as a pressure calibrant.

**Compression of  $\text{Sc}_2\text{BDC}_3$  using Methanol.** Upon immersion of a crystal of  $\text{Sc}_2\text{BDC}_3$  in methanol without added pressure (in a capillary), the unit cell expanded as methanol diffused into the framework (Table 1, Fig. 1a). The density of methanol modelled in the pores equates to an uptake of  $3.3 \text{ mmol g}^{-1}$ , in reasonable agreement with the experimental isotherm which shows a reversible uptake of  $\approx 4 \text{ mmol g}^{-1}$  (or 1.2 molecules per triangular ‘channel’, Fig. S2).

A separate single crystal was then loaded into a DAC using methanol as the hydrostatic liquid. On loading to 0.3 GPa, the unit cell volume expanded further, as a result of additional methanol being forced into the porous framework at a higher concentration (Table 1). Although the inclusion of small molecules has been observed before in the pores of much larger MOFs (with nano-sized cavities) at high-pressure, these did not give ordered sites in the pores.<sup>13,14,28</sup> Expansion of the framework continued to 0.6 GPa, with the unit cell volume increasing by  $41.4 \text{ \AA}^3$  (0.7%). On further increasing the pressure to 1.1 GPa, the volume began to decrease, with the cell volume continuously decreasing until the maximum pressure of 3.0 GPa was reached (Fig. 3a). The compressibility of the unit cell dimensions is strongly anisotropic (Figs S3 to S5) so that while the *a*-axis follows the same trend as the unit cell volume, showing an initial increase up to 1.1 GPa, followed by a continuous decrease to 3.0 GPa, both the *b* and *c*-axes decrease in length for the entirety of the increasing pressure regime.

**Table 1.** Number of methanol molecules, methanol density, occupancy of Site 1 and Site 2 methanol molecules (calculated using the SQUEEZE algorithm) in  $\text{Sc}_2\text{BDC}_3$  are shown. Freely refined occupancies from the model are given in Table S1 in the ESI. The 0.0 GPa data set refers to  $\text{Sc}_2\text{BDC}_3$  which was ‘immersed’ in methanol at ambient pressure at 298 K.

Pressure (GPa)	Total No. of MeOH molecules /unit cell	MeOH density ( $\text{gcm}^{-3}$ )	Occupancy of Site-1 MeOH molecules	Occupancy of Site-2 MeOH molecules
0.0	9	0.23	0.5	0.39
0.3	32	0.76	1.0	0.49
0.6	39	0.91	1.0	0.71
1.1	41	0.96	1.0	0.79
1.4	38	0.92	1.0	0.69
1.6	42	1.01	1.0	0.80
2.3	39	0.98	1.0	0.75

The anisotropic compression of the unit cell dimensions (and volume) can be explained by analysing the uptake of methanol

molecules within the pores of  $\text{Sc}_2\text{BDC}_3$ . On initially surrounding the sample with methanol at ambient pressure, the guest molecules occupy two distinct sites, though the identity of the non-hydrogen atoms could not be identified. Site 1 (Fig. 1a&b) is only half occupied at ambient pressure (and disordered about a 2-fold axis). Pairs of Site 1 methanol molecules sit on either side of the ‘gaps’ formed between Group 1 ligands. Site 2 is also only partially occupied at ambient pressure and is located on either side of the ‘gaps’ between Group 2 ligands (Fig. 1a & c). Site 1 and Site 2 molecules occupy the channels which run along the  $a$ -axis, resulting in a stacking of methanol molecules along the principal pore direction (Fig. 1). The  $a$ -axis expands on uptake of methanol, so it appears that the filling of both sites and subsequent stacking of methanol molecules along the pore direction is responsible for the expansion of the  $a$ -axis and contraction along the  $b$  and  $c$ -axes. Such behaviour in materials is often termed negative linear expansion, as commonly seen in ‘wine-rack’ (or similar) framework topologies.<sup>29</sup>

Inclusion of methanol molecules does not result in a change of symmetry, unlike the transition from  $Fddd$  to  $C2/c$  on uptake of  $\text{CO}_2$  guest molecules observed previously. On increasing pressure to 0.3 GPa, Site 1 becomes fully occupied, while the Site 2 occupancy also increases (to 0.5). On increasing pressure above 0.3 GPa, the occupancy of Site 2 molecules continues to increase, reaching a peak occupancy of 0.8 at 1.1 GPa. Increase of the  $a$ -axis (and volume expansion) continues to 0.6 GPa as more methanol molecules occupy Site 2. The non-hydrogen atom bonding distances between pairs of Site 1 (2.701 Å) and Site 2 (2.422 Å) molecules at 0.6 GPa is in the range of H-bonding interaction distances observed for hydroxyl groups in the solid state, although the guest-guest distance between pairs of Site 2 molecules is towards the lower end of this range. The minimum O...O distance in methanol crystallised at 4.0 GPa (ca. 40,000 bars), for example, measures 2.425 Å.<sup>30</sup> We postulate that the increased uptake at higher pressures, resulting in short guest-guest contact distances is the reason why Site 2 is not readily fully occupied.

Contraction of both the  $a$ -axis and volume starts to occur above 0.6 GPa, where the swelling effect caused by continuous inclusion of methanol molecules stacking along the  $a$ -axis is overcome. Instead, compression of the  $a$ -axis, and therefore volume reduction, is favoured. No appreciable increase in methanol density is observed above 1.1 GPa, and therefore direct compression of the framework takes place to 3.0 GPa. Amorphization of  $\text{Sc}_2\text{BDC}_3$  in methanol does not take place up to 3.0 GPa. This behaviour is not dissimilar to that of MOF-5, where the onset of amorphization can be delayed by guest inclusion, with MOF-5 becoming amorphous above 3.2 GPa upon hydrostatic compression using diethylformamide as a hydrostatic medium.<sup>13</sup> More recently, in a high pressure study of the flexible framework  $\text{NH}_2\text{-MIL-53-(In)}$ , guest inclusion also occurs and pressure-induced amorphization does not take place until >20 GPa.<sup>31</sup>

GCMC simulations were performed in order to understand site filling by methanol molecules in  $\text{Sc}_2\text{BDC}_3$  and to determine whether the orientations (C and O positions) of the methanol molecules can be determined. Density distributions of adsorption sites were obtained as a function of loading for the structures obtained at ambient pressure, and 0.6 GPa, in order to elucidate whether any subtle changes in the framework at higher pressures gave rise to preferential adsorption sites, as seen previously for  $\text{CO}_2$  in  $\text{Sc}_2\text{BDC}_3$ . No differences were observed (see Figure S6), so that only the simulations on the structure determined at 0.6 GPa are shown here. At low loading in both the ambient and 0.6 GPa structures, methanol molecules are preferentially adsorbed at Site 1 (Figure 4). As loading increases to 21 molecules/unit cell (mol./uc.), Site 1 becomes saturated, and adsorption of methanol molecules at Site 2 begins in both the ambient and 0.6 GPa structures. A further increase in loading (beyond 32 mol./uc.) results

in a greater uptake of methanol molecules at Site 2. The pore filling order of both sites would therefore appear to match the order of uptake of methanol molecules observed in our high pressure experiments, and is independent of any subtle changes in the framework at elevated pressures.

**Figure 3a.** Unit cell volume of  $\text{Sc}_2\text{BDC}_3$  in methanol and Fluorinert FC-77 as a function of pressure. The open diamond refers to the ambient structure surrounded with MeOH in a capillary.

**Figure 3b.** Unit cell volume of  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$  in methanol (blue squares) and Fluorinert FC-77 (red squares) as a function of pressure (Closed red squares,  $C2/c$  structure; open red squares,  $Fdd2$  structure, with unit cell halved for comparison with monoclinic structure).

In an effort to further elucidate the pore filling mechanism and examine further guest-guest interactions, molecular dynamics simulations were performed using the framework  $\text{Sc}_2\text{BDC}_3$  structure measured when immersed in methanol, as well as for each of the structures in Table 1, at a loading of 39-41 mol./u.c. This corresponds to a fully saturated framework, with three methanol molecules per pore.

In order to determine whether the adsorbed molecules interact with each other through hydrogen bonds, radial distribution functions were calculated from the molecular dynamics simulations by analysing the distances between the oxygen and hydroxyl H-atoms of different molecules of adsorbed methanol, and H-bonds were located in the MD snapshots. Such an analysis should determine the origin of the preferred uptake in Site 1, as well as suggesting the most likely orientation of methanol molecules in the sites, because it was not possible to distinguish  $\text{CH}_3$  and  $\text{OH}$  groups by XRD. Therefore, we determined site specific radial distribution functions distinguishing between atoms in pairs of methanol molecules with the following locations: Site 1-Site 1; Site 2-Site 2, Site 1-Site 2). Only distances between atoms of

different molecules were examined. Similar results were observed for all high-pressure data sets – only the results obtained by modelling using the framework positions determined in contact with 0.6 GPa of methanol are shown here (Figure 5).

**Figure 4.** Density distribution plots for the adsorption of methanol in  $\text{Sc}_2\text{BDC}_3$ . Each plot shows the locations of methanol molecules adsorbed at a particular loading. Each dot represents the position of the centre of mass of a molecule during the GCMC simulation. Red and blue regions denote adsorption at Site 1 and Site 2 respectively.

For three of the four atomic pairs analysed, the separation distance between oxygen and hydrogen atoms lies between 1.50 and 2.25 Å, characteristic for hydrogen bonds (Figure 5). The highest occurrence of hydrogen bonds occurs between pairs of Site 1 methanol molecules. Methanol molecules adsorbed on Site 2 are equally likely to form hydrogen bonds with other Site 2 molecules and also with hydrogen atoms of methanol molecules adsorbed within the same pore at Site 1. By contrast, oxygen atoms of methanol molecules adsorbed on Site 1 only rarely form hydrogen bonds with hydrogen atoms of methanol molecules at Site 2. The presence of hydrogen bonds of type Site 1-to-Site 1, Site 2-to-Site 2, and Site 2-to-Site 1 is illustrated in the simulation snapshot of the ‘immersed’ ambient pressure structure (Figure 6). Site 1 methanol molecules exhibit a strong preference for hydrogen bonding to

other Site 1 molecules, indicating that the arrangement of framework atoms near Site 1 is more conducive to hydrogen bond formation than the geometry at Site 2. The snapshot also suggests that orientation of methanol C and O atoms with the O atoms closer to the gaps (and other Site 1 methanol molecules) is favoured. The high incidence of hydrogen bonds between pairs of Site 1 molecules increases the site stability and results in a preferential filling of Site 1. By contrast, methanol molecules adsorbed at Site 2 are able to form hydrogen bonds less frequently, and exhibit no preference in interacting with Site 1 or Site 2 methanol molecules.

**Figure 5.** Radial distribution functions for methanol molecules adsorbed in  $\text{Sc}_2\text{BDC}_3$ . Site 1 O corresponds to the O-atom of a methanol molecule adsorbed on Site 1, Site 2 H to the OH group H-atom of a methanol molecule adsorbed on Site 2, and so on.

**Compression of  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$  using Fluorinert FC-77.** In order to determine the effect of derivatising the terephthalate linker on the uptake of guest molecules at pressure, the effect of pressure on  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$  was also studied. At ambient pressure and temperature,  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$  crystallises in the monoclinic space group  $C2/c$ ;  $a = 8.6786(3)$  Å,  $b = 34.4286(13)$  Å,  $c = 11.0628(4)$  Å,  $\beta = 110.482(2)^\circ$  and  $V = 3096.4(2)$  Å<sup>3</sup>. Topologically, the framework is very similar to the native  $\text{Sc}_2\text{BDC}_3$  structure composed of the same 1D channels (Fig. 7). The  $\text{NO}_2$  group however is disordered over two positions by an inversion centre (Group 1) and by a two-fold rotation axis (Group 2). This results in the orthorhombic  $Fddd$  symmetry being broken with a smaller aperture formed between pairs of Group 1 and Group 2 ligands.

In order to ascertain whether a crystalline-to-amorphous phase transition is observed in  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$  at high pressure (as was observed with  $\text{Sc}_2\text{BDC}_3$ ), and to de-convolute the effect of pressure and solvent inclusion, a separate high-pressure experiment was carried out on  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$  using Fluorinert FC-77. On increasing pressure from ambient to 0.3 GPa, direct compression of the framework occurs, and is reflected in the compressibility of all three axes and the volume (Fig. 3b, and Fig. S8 to S10). On increasing pressure further to 0.8 GPa, a single-crystal to single-crystal phase transition occurs with a resulting crystallographic symmetry change from space group  $C2/c$  to  $Fdd2$ ;  $a = 19.610(6)$  Å,  $b = 32.864(8)$  Å,  $c = 8.6757(16)$  Å and  $V = 5591(2)$  Å<sup>3</sup>. The new phase ( $\text{Sc}_2(\text{NO}_2\text{-BDC})_3\text{-HP}$ ), is formed by a rotation of the  $\text{ScO}_6$  octahedra and is characterized by a drastic distortion (and collapse) of the 1-D porous channels (Fig. 7). Above 0.8 GPa, the framework volume continued to reduce with the compressibility decreasing with increasing pressure. Above 2.6 GPa, the sample underwent an irreversible amorphization. This amorphization

pressure for the nitro-form is much higher than that for  $\text{Sc}_2\text{BDC}_3$  (0.4 GPa), indicating the stabilisation effect of the presence of the bulk nitro group. The compressibility of the  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3\text{-HP}$  phase is anisotropic, with the  $\approx 8 \text{ \AA}$  axis (previously the  $a$ -axis in  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$ ) actually increasing (modestly by 0.03  $\text{\AA}$ ) in length between 0.8 to 2.2 GPa. Unlike the guest-driven increase in the  $\approx 8 \text{ \AA}$   $a$ -axis observed before for the native  $\text{Sc}_2\text{BDC}_3$ , the increase here is actually caused by a continued tilting of the  $\text{ScO}_6$  octahedra to higher pressures. The gradient of the unit cell compression decreases in Fluorinert FC-77 as a function of pressure as the sample becomes less compressible with increasing pressure (Fig 3b). This behaviour is typical for molecular materials where direct compression takes place.

**Figure 6.** Arrangement of methanol molecules within  $\text{Sc}_2\text{BDC}_3$  from the immersed ambient pressure structure coordinates. Molecules adsorbed at Site 1 are shown in blue, while molecules adsorbed at Site 2 are shown in orange. Hydrogen bonds are indicated using red dashed lines.

**Compression of  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$  using Methanol.** On initially loading a crystal of  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$  to 0.21 GPa using methanol as the hydrostatic medium, the unit cell volume decreased by 32.69  $\text{\AA}^3$  (0.52 %, Fig. 3b). Increasing pressure further to 0.9 GPa, the volume continued to decrease, above 0.9 GPa, a volume decrease is observed which continued to 3.3 GPa. Unfortunately, unlike the unfunctionalized  $\text{Sc}_2\text{BDC}_3$  sample, the high-pressure data was not of high enough quality to be able to extract atomic structural information on the pore contents, nor model the uptake of solvent. Nevertheless, the contrasting compression behaviour when compared with a non-penetrative hydrostatic fluid (Figure 3b) indicates that methanol uptake does occur, and that its inclusion stabilises the framework against structural transition and very rapid volume decrease (as observed in Fluorinert). On increasing pressure to 0.2 GPa, and then further to 0.9 GPa, the  $a$ -axis increases (by 0.11%), while the  $b$  and  $c$ -axes both decrease by 0.13 and 0.28% respectively (Fig. S11 to S13). This behaviour is similar in type to that of  $\text{Sc}_2\text{BDC}_3$  in methanol, where the axis along which the porous channels of the framework run (which is also the  $\approx 8 \text{ \AA}$   $a$ -axis), increases in length. The increase in length of the

$a$ -axis in  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$ , is much less drastic and this reflects the lower uptake. This is unsurprising considering the presence of the bulky  $\text{NO}_2$  side groups, with the overall effect of pressure causing a volume reduction to 0.9 GPa, rather than expansion which is observed in  $\text{Sc}_2\text{BDC}_3$  to 0.6 GPa. This result is also consistent with the methanol adsorption isotherm under ambient pressure conditions, which shows a significantly reduced uptake of methanol compared to the native  $\text{Sc}_2\text{BDC}_3$  (Fig S2).

**Figure 7.** Structural phase transition of  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$  (upper figure) to  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3\text{-HP}$  (lower figure) at 0.8 GPa. Note: the  $\text{ScO}_6$  octahedra tilt causing the collapse of the porous network. Colour scheme: O, red; C, grey; N, blue and  $\text{ScO}_6$  octahedra, green.

Above 0.9 GPa, the  $a$ -axis (and volume) contracts more rapidly. This behaviour is typical of porous MOFs which display two regions of different compressibility. In Cu-BTC, this transitional behaviour was attributed to hyperfilling of the pores by the hydrostatic liquid followed by a sudden emptying of the pores at higher pressures, resulting in a material which becomes more compressible at higher pressures.<sup>14,28</sup> We, however cannot conclude that this occurs in  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$ , as similar behaviour is observed in  $\text{Sc}_2\text{BDC}_3$ , where the methanol content actually reached saturation by 1.1 GPa, and remains in the pores until at least 2.3 GPa, despite clearly showing two regions of different compressibility. Until now, it has not been possible to measure the uptake of methanol above 2.3 GPa in  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$ , and further work is required to ascertain whether guest uptake increases, decreases or reaches a plateau at the higher pressures.

## CONCLUSIONS

The compressibility of both  $\text{Sc}_2\text{BDC}_3$  and  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$  MOFs are highly sensitive to the pressure-transmitting medium used. For  $\text{Sc}_2\text{BDC}_3$  in Fluorinert FC-77, the molecules are too bulky to penetrate the pore volume and so the framework compresses upon

loading to 0.1 GPa. Increasing the pressure further to 0.4 GPa results in a crystalline-to-amorphous phase transition which is fully reversible. Raman spectroscopy suggests that loss of crystallinity is possible without bond breaking. Using methanol as a medium, molecules enter the pores of  $\text{Sc}_2\text{BDC}_3$ , and can be located in two distinct sites, Sites 1 and 2. The first is filled by 0.3 GPa: upon increasing pressure, the occupancy of the less favourable Site 2 increases as more methanol molecules are forced into the pores until a maximum uptake is observed at  $\approx 1.1$  GPa. The crystallinity of  $\text{Sc}_2\text{BDC}_3$  is retained during methanol-mediated compression up to 3.0 GPa, well beyond the limit when no further methanol uptake occurs. This behaviour was further investigated using both GCMC and molecular dynamics simulations, which further supported the order of inclusion of adsorbed methanol molecules, filling Site 2 at higher pressures. The propensity for hydrogen bonding was also investigated, and indicates that H-bonding interactions occur between molecules in each site and that H-bonding between adjacent Site 1 molecules helps orient the methanol molecules.

The pore volumes in  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$  are smaller than those in  $\text{Sc}_2\text{BDC}_3$  due to the nitro groups. This alters the way in which the unit cell volume changes in order to accommodate increasing pressure. As is the case with  $\text{Sc}_2\text{BDC}_3$ , compressing  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$  to 0.4 GPa in Fluorinert FC-77 resulted in direct compression of the framework, but increasing the pressure further to 0.8 GPa resulted in a single-crystal to single-crystal phase transition ( $C2/c$  to  $Fdd2$ ) with a concomitant distortion of the 1-D porous channels. Between 0.8 and 2.6 GPa, the framework showed continued reduction in volume with the compressibility decreasing with increasing pressure. Above 2.6 GPa, the sample underwent an irreversible amorphization, though the pressure at which this happens is 6.5 times greater than that for the unfunctionalised  $\text{Sc}_2\text{BDC}_3$ , demonstrating the increased stability of the crystalline phase of the framework containing the derivatised BDC ligand. In  $\text{Sc}_2\text{BDC}_3$ , the pressure-induced inclusion of methanol caused a swelling of the unit cell whereas in  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$  we only see a decrease in volume: it is likely that the uptakes of methanol is much lower. The high-pressure data for  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$  is not of high enough quality to extract pore content information, but methanol uptake in  $\text{Sc}_2(\text{NO}_2\text{-BDC})_3$  is observed at ambient pressures and can be inferred at high pressures from the increase in stability of the  $C2/c$  phase and its compressibility behaviour.
